

# The Minimum Wage and Search Effort

Camilla Adams, Jonathan Meer and CarlyWill Sloan\*

September 27, 2018

## Abstract

Labor market search-and-matching models posit supply-side responses to minimum wage increases that may lead to improved matches and lessen or even reverse negative employment effects. Yet there is no empirical evidence on this crucial assumption. Using event study analysis of recent minimum wage increases, we find that increases to minimum wage do not increase the likelihood of searching, but do lead to large yet very transitory spikes in search effort by individuals already looking for work. The results are not driven by changes in the composition of searchers.

# 1 Introduction

Do minimum wage increases affect search effort by job seekers? Predictions of the impact of the minimum wage in search-and-matching models of the labor market depend heavily on endogenous search effort responses (Acemoglu, 2001; Flinn, 2006; Ahn et al., 2011). In these models, the increased cost of hiring can be offset by the supply side, where workers search more and longer, leading to better job matches.<sup>1</sup> Indeed, this is one of the primary reasons posited for the lack of employment response to the minimum wage sometimes seen in the empirical literature (e.g. Allegretto et al., 2011).

We investigate the effect of minimum wage increases on job search effort utilizing data from the Current Population Survey (CPS) and the American Time Use Survey (ATUS). We exploit the staggered nature of CPS and ATUS interviews and use an event-study approach, leveraging within-state variation in the adoption of minimum wage changes. We account for shocks affecting a particular state in a given year as well as month effects to control for seasonality, and individual demographic characteristics. Intuitively, we compare the outcomes in each month near the treatment date to the outcomes for otherwise-identical individuals in the same state and year whose survey period was not near a treatment date.

We find no evidence that the minimum wage has persistent effects on search effort; the likelihood of searching does not increase in the aftermath of minimum wage increases. However, there is a large yet transitory increase in the intensive margin of search effort, concentrated in the month of the minimum wage increase, that fades almost immediately. There is no short-run increase in the employment rate nor changes in observable characteristics of

---

<sup>1</sup>Burdett and Mortensen (1998) suggest that search frictions can generate monopsonist competition, leading to employment increases as a result of minimum wage increases.

searchers, suggesting that our results are not driven by changes in the composition of job seekers. These findings are robust to the inclusion of demographic controls, the duration of unemployment benefits, and month-by-year fixed effects that account for any idiosyncratic national-level variation in a given month. We also conduct a permutation test for our search duration results in which we randomly assign minimum wage increases across time periods and show that these results do not appear to be due to chance.

Our results call into question the assumption underpinning search-and-matching models as applied to analysis of the minimum wage – namely, that more workers will enter the labor market and each worker will search harder, increasing the returns to firm vacancy postings. Importantly, we find minimum wage increases do not induce individuals to begin searching. While we find that minimum wage increases yield significant increases in worker search effort on the intensive margin, they are transitory.

Our results contribute to the existing literature in several ways. To the best of our knowledge, we provide the first direct evidence of an important input into search-and-matching models as applied to the minimum wage. We also add to the empirical literature on job search behavior. These studies consider the role of macroeconomics conditions (e.g. Aguiar et al., 2013; Mukoyama et al., 2018), safety net programs including but not limited to unemployment benefits (e.g. Clemens et al., 2015; Krueger and Mueller, 2010; Krueger and Meyer, 2002), and the impact of wage dispersion (Mueller, 2010). Our paper is also related to recent work on online job search (Kroft and Pope, 2014; Brown and Matsa, 2016; Faberman and Kudlyak, forthcoming), although we consider all types of search effort. Finally, we add to a small but growing literature that investigates the effect of minimum wage on the supply side

of the labor market, which primarily focuses on commuting and relocation patterns. The results in this nascent literature thus far have similar findings: Cadena (2014), McKinnish (2017), and Pérez (2018) respectively find evidence suggesting that workers are less likely to locate in, more likely to commute out of, and less likely to commute into areas that increase their local minimum wages.

The paper proceeds as follows: in Section 2, we discuss the Current Population Survey and the American Time Use Survey, our primary data sources. Section 3 describes our econometric approach and Section 4 presents our results. We conclude in Section 5.

## 2 Data

### 2.1 Current Population Survey

We use the 2003-2016 basic monthly survey of the CPS for data on employment, demographics and searching status, consisting of 2.2 million respondents. We use only a household's first interview to avoid selection problems; the CPS does not prioritize locating respondents who move after their first interview (Dixon, 2002; U.S. Bureau of Labor Statistics, 2006).<sup>2</sup>

Every year, the CPS basic monthly survey includes about 160,000 first-time respondents.

We define job search using the CPS's question about looking for work over the previous four weeks, recording it for all those not in the labor force, and those who are unemployed but

---

<sup>2</sup>It might seem natural to estimate a within-individual specification, but selection issues may arise due to household attrition. Those with lower income and education, and thus more likely to be affected by a minimum wage change, are less likely to be observed multiple times.

not on temporary layoff (851,731 respondents).<sup>3</sup> Employment is evaluated according to the respondent’s reported employment status based on her activities in the week that includes the 12th of the month. Panel A of Table 1 provides summary statistics on respondents, job searchers and the unemployed. Among those in our potential-searcher sample, 11 percent report searching in the previous month.

## 2.2 American Time Use Survey

The CPS has the advantage of large sample size, but does not ask about the intensive margin of search effort. We therefore supplement those data with the 2003-2016 waves of the American Time Use Survey.<sup>4</sup> Individuals are sampled for the ATUS from the CPS, and are surveyed approximately three months after their final CPS survey. The ATUS includes a one-time twenty-four hour diary detailing daily activities of respondents in 400 categories. Each year, the ATUS records a time-use diary for about 13,000 respondents.

We consider an individual to be searching for work if they report non-zero time searching for work on the day of their time diary. As such, an individual can be considered searching even if they are categorized as not being in the labor force by the Bureau of Labor Statistics definition, which is reported according to the activities in the seven days preceding the ATUS interview. We define time spent on job search broadly, including all time spent searching and

---

<sup>3</sup>Employed individuals and those unemployed but on layoff are not asked about job search, since “working or having a job takes precedence over looking for work” in the CPS’s classification scheme (U.S. Bureau of Labor Statistics, 2015). Some of those classified as not in the labor force are not asked this question, while others are. We define all those classified as not in the labor force who are not asked the question as non-searchers, since not being in the labor force is, at least in part, defined by lack of search effort. Dropping those individuals from the sample entirely does not impact our results in a meaningful way. There are also a small number of what appear to be coding errors for employed respondents; about 200 are coded as searchers in the entire 2.2-million-observation data set. We drop them from the universe of potential searchers; including them does not alter our results.

<sup>4</sup>The disadvantage of these data is that the ATUS lacks the sample size to examine effects by subgroups of interest conditioning on positive search effort.

interviewing, as well as activities that are categorized as related to job search. This sample includes all 181,335 ATUS respondents filing a time-use diary between 2003 and 2016. Panel B of Table 1 provides summary statistics on respondents, job searchers, and the unemployed; note that the ATUS oversamples weekend dates. About one percent of the entire sample reports engaging in search-related activities, with about 15 percent of the unemployed doing so. The unconditional mean time spent searching by all individuals in the sample search is 1.5 minutes a day; the unemployed and those who report non-zero search (including those concurrently employed and searching) do so for 21 and 133 minutes, respectively.

## 2.3 Minimum Wage

Our minimum wage data is compiled from the Bureau of Labor Statistics website, supplemented with corrections and additions from Meer and West (2016) and Clemens et al. (2018). We exploit 259 state-level minimum wage changes across 2003-2016, taking the most expansive definition of such changes, including those induced by increases in the federal minimum wages and those linked to inflation indexing. States experienced an average of six minimum wage changes. The average nominal minimum wage over the time period was \$6.88 (median \$7.25), and the average nominal change was 53 cents (median 50 cents). We define minimum wage in a given month as its value on the first of that month.

### 3 Specification

Our specification captures the short-run dynamic effects of a minimum wage change on the extensive and intensive margins of search effort. We estimate the following equation:

$$\begin{aligned}
 Y_{i,s,t,m,p} = & \sum_{p=-5}^5 \beta_p I(\text{MonthOfTreatment})_p + \beta_c I(\text{AllOtherMonths})_c + \alpha_1 \text{StateYear}_{s,t} \\
 & + \alpha_2 \text{Month}_m + \tau \text{IndividualControls}_{i,s,t,m} + \gamma X_{s,t} + \epsilon_{i,s,t,m,p}
 \end{aligned} \tag{1}$$

$\beta_p$  represents a different coefficient for each of the eleven months, five months before through five months after, centered on the month of minimum wage change. We selected this time frame as the longest one for which there was no overlap between before- and after-periods. All observations that do not fall in this eleven-month window around a treatment are grouped into the excluded category.

We account for state-specific shocks in a particular year that may be correlated with minimum wage increases with state-by-year fixed effects and for seasonal differences with month fixed effects. We also include age and its quadratic, gender, race, a series of indicators for education level, and whether the respondent was interviewed on the weekend.<sup>5</sup> The duration of unemployment benefits available to respondents in state  $s$  for year  $t$  in month  $m$ , measured in weeks, are included in  $X_{m,s,t}$ .<sup>6</sup> Standard errors are multi-way clustered at

---

<sup>5</sup>The weekend status of an interview is only observed in the ATUS.

<sup>6</sup>These data were compiled by Rothstein and Valletta (2017) and supplemented with additional data that we gathered.

the state and year-by-quarter level.<sup>7</sup>

We use our model with both the CPS and the ATUS to explore two main outcome variables: (1) the probability of searching (2) time spent searching (using ATUS data only). We check for pre-trends within a state-year by examining the pattern of coefficients for the months leading up to the minimum wage change. Such trends could reflect potentially biasing spurious correlation or anticipatory effects by prospective workers; regardless, we find no evidence of them.<sup>8</sup>

Another potential concern is that composition of respondents varies systematically in a manner that is correlated with the minimum wage changes we examine, despite the random sampling of respondents by the Bureau of Labor Statistics. Figure A.8 plots the relationship between the monthly treatment-time indicators and demographic variables like age, race, education and gender for the CPS.<sup>9</sup> There is some variation from month to month – for example, sampled respondents tended to be a few months older in the month of minimum wage changes and less educated in the month before an increase relative to the comparison group – but these are unlikely to affect our results, which control for these demographic variables.

---

<sup>7</sup>After accounting for individual characteristics, length of unemployment benefits, seasonality, and within-state-year effects, it is difficult to imagine a shock to search effort that is uncorrelated with those controls, and coincidental solely with the month of a state-specific minimum wage change. Nevertheless, we also add month-by-year (that is, time) effects that account for national-level idiosyncratic shocks in a particular month. The results, in Figures A.6 and A.7, are similar to our main specifications.

<sup>8</sup>As suggested by Borusyak and Jaravel (2016), we perform an F-test on the pre-period coefficients and can reject the existence of pre-trends in outcomes for both datasets. It is also possible that trends in unobservables correlated with treatment and searching behavior could be driving our results. We implement the instrumental variable approach suggested in Freyaldenhoven et al. (2018) and re-estimate our dynamic results. Although this approach yields noisier estimates, our results remain similar for both the ATUS and the CPS.

<sup>9</sup>Sample sizes in the ATUS conditional on demographic characteristics are too small for meaningful inference; there are no unusual patterns or statistically significant effects, but the estimates are quite noisy.

## 4 Results

### 4.1 Current Population Survey

Figure 1 shows that there are no changes in searching status after a minimum wage increase when examining the entire sample. The coefficients are small and precisely estimated, and show that minimum wage increases do not induce prospective workers to begin searching. No coefficient on the likelihood of searching in the period after a minimum wage change is larger than 0.2 percentage points, or a 2 percent increase relative to the baseline. There are no meaningful trends in search status in the five months prior to a minimum wage change. Further, there are no impacts on the probability of not being in the workforce or on the likelihood of employment in the months before and after a minimum wage change. The lack of impact on entry into the labor force provides further evidence that individuals are not more likely to seek a job in the wake of a minimum wage increase. The results on employment suggests that there is no negative selection in the composition of searchers caused by the entry of higher-value searchers into employment; we return to the question of changes in the composition of searchers in Section 4.3, including estimates of results by subgroups.

These results provide precisely-estimated zero results on the extensive margin of search, indicating that minimum wage changes do not increase the number of individuals searching for work. However, the CPS is limited in that it has little data on the intensity of search effort. We therefore turn to the ATUS to examine impacts on that margin.

## 4.2 American Time Use Survey

We begin by replicating the extensive-margin results from the CPS using the smaller ATUS sample. In Figure 2, we find that there are no statistically significant changes in the likelihood of searching for work after a minimum wage increase. The results are small and fairly precise, with no positive coefficient larger than 0.08 percentage points, or 7% of the baseline value. Again, there is no impact on the probability of not being in the workforce and the probability of employment, and there are no trends. There is therefore no evidence of increased likelihood of searching.

We turn to the intensive margin of search effort – the number of minutes spent engaged in job-search-related activity. Figure 3 shows the dynamic effects of minimum wage changes on search duration using the entire sample, including those not in the labor force and those not searching. There is a positive and statistically significant effect of 0.8 minutes, or about 50 percent of the baseline level, but only in the month of the minimum wage increase. The effect in the following months are small and arrayed around zero.

Next, we focus on the unemployed. Figure 4 shows that the likelihood of searching by the unemployed does not change around the treatment periods. As with the whole-sample results in Figure 3, time spent searching only increases in the month of the minimum wage change. Figure 4 shows an increase of 16 minutes per day, or 8 hours extrapolated for the month of the minimum wage change; this amount is about 75 percent of the baseline value. Again, the effect is transitory, with coefficients in the following five months being close to zero.

Finally, we show results for those reporting positive search minutes only. Once again,

the effects are entirely concentrated in the month of the minimum wage change. Figure 5 shows an increase of 75 minutes a day, about 55 percent of the baseline value, and the effect is short-lived. None of the following five months have an effect that is even one-third the size of the effect in the month of the change, and most are much smaller.<sup>10</sup> These results are consonant with the lack of impact on the likelihood of searching: multiplying the effect on non-zero searchers by the prevalence of searchers in the sample yields a value nearly identical to the coefficient estimated using the whole sample.

### 4.3 Changes in the Composition of Searchers

Taken together, our results indicate that there is little or no entry into search activity as a result of minimum wage increases, and increases in search effort among searchers are short-lived. It is difficult to pin down the cause of this pattern, though we can reject the possibility that employment increases around the time of the minimum wage change. If that were the case, it could lead to negative selection of those continuing to search; that is, those still searching are less attractive to employers and thus need to put forth more effort to find employment. This type of selection would not likely lead to the one-month increase in search effort.

However, it is possible that the composition of searchers does change in some other way. For example, if employer preferences for workers change in response to minimum wage increases, there may be offsetting shifts in the likelihood of search by education level (Clemens et al., 2018). Figure A.10 shows these results for the likelihood of searching in the CPS by

---

<sup>10</sup>We replicate these results using an inverse hyperbolic sine transformation, Poisson, and negative binomial model in Figure A.9 There are no meaningful changes in the pattern of results.

education level; as noted above, the ATUS sample is too small to yield meaningful inference for subgroups. There is no evidence that more-educated workers are more likely to search while less-educated workers exit the labor force entirely.<sup>11</sup>

We next investigate whether any observable characteristics of job-seekers changes around minimum wage increases. Again using the CPS, we estimate Equation (1) using respondent characteristics as the outcome variables, restricting the sample to searchers only. The results, in Figure A.11, show little evidence that suggests such changes. There may be a slight increase in the prevalence of high school dropouts among searchers in the month of the minimum wage increase, but the estimate is not statistically significant. Several other coefficients are statistically significant (for example, searchers in the third month after a minimum wage increase are about 1 year older than the comparison group), but as there are dozens of estimates shown in these graphs and no discernible pattern, we do not emphasize these findings.

It is still possible that the composition of job-seekers changes dramatically in response to the minimum wage in a manner that leaves the overall search rate unaffected, but leads to low-activity searchers exiting and high-activity searchers entering the labor market. That is, a minimum wage increase causes those who are searching for a small number of hours to shift to zero search, while inducing entry by individuals who were previously not searching but now search for substantial amounts of time. In that case, our results would reflect unobserved heterogeneity in the monthly cross sections of the data, though would remain an interesting response to minimum wage increases. To the extent that those who begin searching provide more productive matches for employers, this mechanism would be consonant with the search-

---

<sup>11</sup>We also estimate results by age and find no meaningful patterns.

and-matching literature. However, this type of sorting would have to be uncorrelated with the demographic characteristics examined above and for which we control; given the size of the response in Figure 5, this seems unlikely. Moreover, it is difficult to reconcile with the short-lived spike in search effort. On balance, there is very limited evidence for the notion that search activity increases in response to the minimum wage in a manner consistent with theoretical search-and-matching models.

#### 4.4 Placebo Tests

To evaluate the possibility that our search duration results arise from random chance rather than a causal relationship, we estimate Equation (1) on a series of placebo treatments in a method similar to Bertrand et al. (2004). For each permutation, we draw with replacement from a distribution of potential treatment time periods, an eleven month window centered on a minimum wage change based on the true distribution of monthly changes we observe in the actual data. For example, we place greater weight on January and August, when most of the minimum wage changes occur in the data. Unlike the month of change, we place equal weight on year and state probabilities. We then assign each state multiple placebo treatment dates. With draws of simulated changes, we estimate Equation (1) one thousand times.

Figure A.12 compares the actual results from Figure 3 to those estimated from the placebo exercise. Each coefficient in this latter estimate, including the in the month of the minimum wage change, is about zero. Figure A.13 plots the actual coefficient on the distribution of the placebo estimates. For the baseline model including the entire sample, our estimate of the impact in the month of the minimum wage change is greater than 91 percent than the

simulated coefficients.

Figure A.14 makes the same comparison for the sample conditioned on unemployment. Again, the placebo estimates are close to zero. Figure A.15 compares our estimates to the placebo distribution. Effects in months other than the month of the change, are not unusual relative to the simulated coefficients. In the month of the change, though, the estimated coefficient is greater than 96 percent of the placebo estimates. Finally, a similar pattern is seen in Figure A.15, comparing results for non-zero searchers, and Figure A.17, which shows that the estimate during the month of the change is also greater than 96 percent of the simulated coefficients.

We conclude that our findings in the dynamic event-study specifications are highly unlikely to have occurred by chance and that they reflect a transitory increase in search effort on the intensive margin.

## 5 Conclusion

This paper explores the relationship between minimum wage increases and search effort. We estimate the dynamic response of search behavior to increases in the minimum wage and find robust evidence that minimum wage changes increase search effort on the intensive margin but only during the month of the minimum wage change. Perhaps most significantly given its importance to search-and-matching models of the labor market, we show that increasing the minimum wage does not induce individuals not already searching to begin doing so.

This transitory effect, although not predicted by standard labor theory, has been documented in a similar setting. Krueger and Mueller (2010) find that job search responses to

unemployment benefit exhaustion are transitory. Specifically, they document that individuals increase their search effort just before unemployment benefits expire, but that effort declines back to previous levels soon after UI benefits are exhausted. Our findings similarly suggest that the search responses to the increased value of obtaining a job may be short-lived.<sup>12</sup>

Understanding the impact of the minimum wage on different aspects of the labor market, rather than simply equilibrium employment outcomes, is of significant importance given its increasing prevalence as a policy instrument. Our findings suggest the need for greater analysis of not only job search behavior after a minimum wage change, but also of other supply side responses.

---

<sup>12</sup>Faberman and Kudlyak (forthcoming) use high-frequency data from an online job-finding platform to document that the number of applications sent by job seekers drops significantly after the first week of search, providing further evidence of rapidly fading search effort.

Age of respondent	47.04 (17.74)	39.58 (13.36)	47.13 (17.76)	36.22 (15.96)	42.70 (13.36)	56.84 (20.79)
Percent high school dropouts	0.158 (0.365)	0.121 (0.327)	0.158 (0.365)	0.305 (0.460)	0.0940 (0.292)	0.257 (0.437)
Male respondent	0.438 (0.496)	0.535 (0.499)	0.436 (0.496)	0.461 (0.498)	0.489 (0.500)	0.337 (0.473)
White respondent	0.808 (0.394)	0.710 (0.454)	0.809 (0.393)	0.712 (0.453)	0.822 (0.383)	0.797 (0.402)
Survey on Weekend	0.502 (0.500)	0.290 (0.454)	0.504 (0.500)	0.499 (0.500)	0.502 (0.500)	0.502 (0.500)
Weeks unemployment insurance	45.91 (26.28)	51.84 (28.39)	45.84 (26.25)	51.77 (28.37)	45.39 (25.93)	46.03 (26.52)
Observations	181335	2051	179284	8720	112996	59619

This table reports the mean and standard deviation for key variables by searching and unemployment status. Data comes from the Current Population Survey (Panel A) and the American Time Use Survey (Panel B). Column (1) includes the entire sample for each dataset. Columns (2) and (3) include summary statistics for those who report non-zero search (Searchers) and those who do not report searching (Non-Searchers), respectively. Columns (4), (5) and (6) report summary statistics for the unemployed, employed and not in the labor force. Employment is measured for the entire population (including those not in the work force). In the CPS, the entire sample for searching is only measured for 851,731 respondents (all unemployed but not on layoff, and not in the labor force).

Figure 1: Employment and Search (CPS)

(a) Employment Status

(b) Searching Status

(c) Not in the Labor Force

This figure plots coefficients from the regression of employment, searching probability or not in the labor force on months before/after treatment, accounting for state-by-year and month fixed effects. Controls for age (age and  $age^2$ ), education level (indicators for less than a high school degree, high school degree, some college and college graduate or more), race (indicator for white or not), gender (indicator for female or not), and unemployment benefits (week duration of benefits available) are included. The omitted group is all observations not in the 5 months before/after treatment. Standard errors are multi-way clustered for state and year/quarter. Ninety-five percent confidence intervals are presented. Employment status equals one if the respondent is employed and zero if they are unemployed or not in the workforce. Probability of searching is one if the individual reports searching in the last four weeks, regardless of labor force status, and zero if they do not. Not in the work force is equal to one if an individuals is not employed or unemployed. Panels (a) and (c) use 2,199,503 observations and Panel (b) uses 851,731. Data are from the Current Population Survey.

Figure 2: Employment and Search (ATUS)

(a) Employment Status

(b) Searching Status

(c) Not in the Workforce

This figure plots coefficients from the regression of employment or searching probability on months before/after treatment, accounting for state-by-year and month fixed effects. An indicator for week or weekend interview and controls for age (age and  $age^2$ ), education level (indicators for less than a high school degree, high school degree, some college and college graduate or more), race (indicator for white or not), gender (indicator for female or not), and unemployment benefits (week duration of benefits available) are included. The omitted group is all observations not in the 5 months before/after treatment. Standard errors are multi-way clustered for state and year/quarter. Ninety-five percent confidence intervals are presented. Employment status equals one if the respondent is employed and zero if they are unemployed or not in the workforce. Probability of searching is one if the individual reports searching, regardless of employment status, and zero if they do not. Not in the work force is equal to one if an individuals is not employed or unemployed. All panels use 181,335 observations from the American Time Survey.

Figure 3: Minutes Searching for Work: Whole Sample (ATUS)

This figure plots coefficients from the regression of minutes searching for work on months before/after treatment dummies, controlling for state-by-year and month fixed effects. The omitted group is all observations not in the 5 months before/after treatment. An indicator for week or weekend interview and controls for age (age and  $age^2$ ), education level (indicators for less than a high school degree, high school degree, some college and college graduate or more), race (indicator for white or not), gender (indicator for female or not), and unemployment benefits (week duration of benefits available) are included. Standard errors are multi-way clustered for state and year/quarter. Ninety-five percent confidence intervals are presented. Results are estimated using 181,335 observations from the American Time Use Survey.

Figure 4: Searching and Minutes Searching: Unemployed (ATUS)

(a) Searching Status

(b) Minutes Searching for Work

This figure plots coefficients from the regression of searching status or minutes searching for work on months before/after treatment dummies, controlling for state-by-year, and month fixed effects. An indicator for week or weekend interview and controls for age ( $age$  and  $age^2$ ), education level (indicators for less than a high school degree, high school degree, some college and college graduate or more), race (indicator for white or not), gender (indicator for female or not), and unemployment benefits (week duration of benefits available) are included. The omitted group is all observations not in the 5 months before/after treatment. Standard errors are multi-way clustered for state and year/quarter. Unemployment is only measured for those who report being in the workforce. Ninety-five percent confidence intervals are presented. Both results are estimated using 8,720 observations from the American Time Use Survey.

Figure 5: Minutes Searching for Work: Non-Zero Searchers (ATUS)

This figure plots coefficients from the regression of minutes searching for work on months before/after treatment dummies, controlling for state-by-year and month fixed effects. The omitted group is all observations not in the 5 months before/after treatment. An indicator for week or weekend interview and controls for age (age and  $age^2$ ), education level (indicators for less than a high school degree, high school degree, some college and college graduate or more), race (indicator for white or not), gender (indicator for female or not), and unemployment benefits (week duration of benefits available) are included. Standard errors are multi-way clustered for state and year/quarter. Individuals are non-zero searchers if they report any time spent searching (regardless of participation in the workforce). Ninety-five percent confidence intervals are presented. Results are estimated using 2,051 observations from the American Time Use Survey.

## A Appendix

Figure A.6: Dynamic Results for State-by-Year and Month-by-Year Fixed Effects (CPS)

This figure plots coefficients from regression of probability of employment, searching, or daily minutes searching for work on months before/after treatment dummies, controlling for state and month by year fixed effects. Controls for age (age and  $age^2$ ), education level (indicators for less than a high school degree, high school degree, some college and college graduate or more), race (indicator for white or not), gender (indicator for female or not), and unemployment benefits (week duration of benefits available) are included. The omitted group is all observations not in months before/after treatment. Standard errors are multi-way clustered for state and year/quarter. Panel (a) reports results for the probability of employment for the entire sample. Panel (b) presents results for the entire sample and the probability of searching. Panel (c) shows results for the probability of not being in the labor force. Data are from the Current Population Survey.

Figure A.7: Dynamic Results for State-by-Year and Month-by-Year Fixed Effects (ATUS)

This figure plots coefficients from regression of probability of employment, searching, or daily minutes searching for work on months before/after treatment dummies, controlling for state and month by year fixed effects. An indicator for week or weekend interview and controls for age (age and  $age^2$ ), education level (indicators for less than a high school degree, high school degree, some college and college graduate or more), race (indicator for white or not), gender (indicator for female or not), and unemployment benefits (week duration of benefits available) are included. The omitted group is all observations not in months before/after treatment. Standard errors are multi-way clustered for state and year/quarter. Panel (a) reports results for the probability of employment for the entire sample. Panel (b) presents results for the entire sample and the probability of searching. Panel (c) presents results for the entire sample and daily minutes searching for work. Panel (d) and (e) present results for the unemployed for probability of searching and minutes searching respectively. Finally, Panel (f) presents results for those who report non-zero search for minutes searching for work. Data are from the American Time Use Survey.

Figure A.8: Respondent Characteristics (CPS)

(a) Age, Gender, Race

(b) Education

This figure plots coefficients from the regression of level of education indicator variables on months before/after treatment dummies, controlling for state-by-year and month fixed effects. The omitted group is all observations not in the 5 months before/after treatment. Standard errors are multi-way clustered for state and year/quarter. Each graph uses the entire sample of 2,199,503 observations. Figure (a) shows results for respondent age, gender and race. Figure (b) shows results for respondent education level. For figure (b) the outcome variable for the upper left graph is a one for all individuals who complete less than a high school degree and zero for all others. For the upper right graph, the outcome variable is one for those with only a high school degree and zero for everyone else. The outcome variable for the lower left graph is one for those who complete more than a high school degree, but less than a four year college degree, and zero for all others. Finally, the outcome variable for the bottom right graph takes a value of one for those with a college degree or more and zero for anyone with less than a four year college degree. Data are from the Current Population Survey.

Figure A.9: Alternate Specifications for Minutes Searching: Non-Zero Searchers (ATUS)

(a) Original Results

(b) Inverse Hyperbolic Sine

(c) Poisson

(d) Negative Binomial

This figure plots coefficients from the regression of minutes searching for work on months before/after treatment dummies, controlling for state-by-year and month fixed effects. The omitted group is all observations not in the 5 months before/after treatment. An indicator for week or weekend interview and controls for age (age and  $age^2$ ), education level (indicators for less than a high school degree, high school degree, some college and college graduate or more), race (indicator for white or not), gender (indicator for female or not), and unemployment benefits (week duration of benefits available) are included. Standard errors are multi-way clustered for state and year/quarter. Individuals are non-zero searchers if they report any time spent searching (regardless of participation in the workforce). Ninety-five percent confidence intervals are presented. Panel (a) is a replication of Figure 4. Panel (b) transforms minutes searching for work using inverse hyperbolic sine. Panel (c) presents results for the Poisson specification and Panel (d) shows results for the negative binomial specification. Data are from the American Time Use Survey.

Figure A.10: Search by Education Level (CPS)

(a) High School Dropouts

(b) High School Degree Only

(c) Some College

(d) College Degree or More

This figure plots coefficients from the regression of searching probability on months before/after treatment, accounting for state-by-year and month fixed effects. Controls for age ( $age$  and  $age^2$ ), education level (indicators for less than a high school degree, high school degree, some college and college graduate or more), race (indicator for white or not), gender (indicator for female or not), and unemployment benefits (week duration of benefits available) are included. The omitted group is all observations not in the 5 months before/after treatment. Standard errors are multi-way clustered for state and year/quarter. Ninety-five percent confidence intervals are presented. Probability of searching is only recorded for the unemployed and some not in the labor force. Data are from from the Current Population Survey.

Figure A.11: Characteristics of Searchers (CPS)

(a) Age, Gender, Race

(b) Education

This figure plots coefficients from the regression of level of education indicator variables on months before/after treatment dummies, controlling for state-by-year and month fixed effects. The omitted group is all observations not in the 5 months before/after treatment. Standard errors are multi-way clustered for state and year/quarter. Each graph uses the sample of searchers (123,289 observations). Figure (a) shows results for respondent age, gender and race. Figure (b) shows results for respondent education level. For figure (b) the outcome variable for the upper left graph is a one for all individuals who complete less than a high school degree and zero for all others. For the upper right graph, the outcome variable is one for those with only a high school degree and zero for everyone else. The outcome variable for the lower left graph is one for those who complete more than a high school degree, but less than a four year college degree, and zero for all others. Finally, the outcome variable for the bottom right graph takes on a value of one for those with a college degree or more and zero for anyone with less than a four year college degree. Data are from the Current Population Survey.

Figure A.12: Placebo Results: Entire Sample (ATUS)

(a) Minutes Searching for Work Results

(b) Placebo Results

This figure plots coefficients from regression of daily minutes searching for work on months before/after treatment dummies, controlling for state-by-year and month fixed effects. An indicator for week or weekend interview and controls for age (age and  $age^2$ ), education level (indicators for less than a high school degree, high school degree, some college and college graduate or more), race (indicator for white or not), gender (indicator for female or not), and unemployment benefits (week duration of benefits available) are included. The omitted group is all observations not in months before/after treatment. Standard errors are multi-way clustered for state and year/quarter. Panel (a) is a replication of Figure 2. Panel (b) presents placebo results from 1000 replications. The mean placebo coefficients and mean 95 percent confidence intervals are plotted for Panel (b).

Figure A.13: Density of Placebo Coefficients: Entire Sample (ATUS)

Above are the resulting distributions of 1,000 placebo coefficient estimates of Equation (1) for minutes searching for work. The lines represent the coefficients estimated in our true data for daily minutes searching for each time period.

Figure A.14: Placebo Results: Unemployed (ATUS)

(a) Minutes Searching for Work Results

(b) Placebo Results

This figure plots coefficients from regression of probability of searching or minutes searching for work on months before/after treatment dummies, controlling for state by year and month fixed effects. Standard errors are multi-way clustered for state and year/quarter. An indicator for week or weekend interview and controls for age (age and  $age^2$ ), education level (indicators for less than a high school degree, high school degree, some college and college graduate or more), race (indicator for white or not), gender (indicator for female or not), and unemployment benefits (week duration of benefits available) are included. The omitted group is all observations not in months before/after treatment. Only those who report unemployment are included. Panel (a) is a replication of Figure 3 panel (a). Panel (b) shows placebo results from 1000 replications. The mean placebo coefficients and mean 95 percent confidence intervals are plotted for Panel (b).

Figure A.15: Density of Placebo Coefficients: Unemployed (ATUS)

Above are the resulting distributions of 1,000 placebo coefficient estimates of Equation (1) for minutes searching for work. The lines represent the coefficients estimated in our true data for daily minutes searching for each time period. Only the unemployed are included.

Figure A.16: Placebo Results: Non-Zero Searchers (ATUS)

(a) Minutes Searching for Work Results

(b) Placebo Results

This figure plots coefficients from regression of probability of searching or minutes searching for work on months before/after treatment dummies, controlling for state by year and month fixed effects. Standard errors are multi-way clustered for state and year/quarter. An indicator for week or weekend interview and controls for age (age and  $age^2$ ), education level (indicators for less than a high school degree, high school degree, some college and college graduate or more), race (indicator for white or not), gender (indicator for female or not), and unemployment benefits (week duration of benefits available) are included. The omitted group is all observations not in months before/after treatment. Only those who report non-zero search are included. Panel (a) is replication of Figure 4. Panel (b) shows placebo results from 1000 replications. The mean placebo coefficients and mean 95 percent confidence intervals are plotted for Panel (b).

Figure A.17: Density of Placebo Coefficients: Non-Zero Searchers (ATUS)

Above are the resulting distributions of 1,000 placebo coefficient estimates of Equation (1) for minutes searching for work. The lines represent the coefficients estimated in our true data for daily minutes searching for each time period. Only the those who report non-zero search are included.
